Abstract

The automatic recognition of music scores is a key process for the electronic treatment of music information. In this paper, we present the segmentation module of an OMR system. The proposed approach is based on the use of projection profiles for the location of elementary symbols that constitute the music notation. An extensive experimentation was made with the help of a tool developed to this purpose. Reported results shown a high efficiency in the correct location of elementary symbols.

1 Introduction

Systems for music score recognition are traditionally called *OMR* (*Optical Music Recognition*); this term is tightly linked to *OCR* (*Optical Character Recognition*) that defines systems for automatic reading of textual documents. Strictly speaking, *OCR* refers to approaches based on the segmentation and recognition of single characters. However, music notation has a two dimensional structure since in a staff the horizontal position denotes different execution time for notes, whereas the vertical position denotes the height of the note [1].

In papers concerning *OMR* (a complete survey from 1960s to 1990 is [2]), the definition of basic symbols is tightly related to the methods considered for symbol extraction and recognition. Basically, there are two main approaches. We can consider the symbols to be recognized as (i) the connected components remaining after staff lines removal (chord, beam with notes, etc.), or (ii) the elementary symbols such as note heads, that can be composed to build music symbols [3]. With the first approach the symbols can be easier segmented, however, the number of different symbols is very high. A complete analysis of music symbols and related semantic has been conducted in MOODS project [4].

A problem addressed in music score segmentation is the presence of staff lines that touch the elementary symbols. The removal of overlapping lines requires a complex process of reconstruction of touched symbols (e.g., [3]), with corresponding loss of information. As a consequence some authors preferred to recognize symbols without removing the portion of lines crossing them. For these purposes, the use of projection profiles is very common. The segmentation method described in this paper is based on an extensive use of projection profiles, for locating elementary symbols without removing staff lines.

2. System Overview

The work reported in this paper is part of O^3MR project (Object Oriented Optical Music Recognition), that is an OMR system directly connected to the music editor of project MOODS (Music Object Oriented Distributed System), an ESPRIT IV HPCN project [4]. The general architecture of O^3MR is based on four main components :

Segmentation – the music sheet is processed with the aim of extracting the basic symbols and their positions.

Basic Symbol Recognition – this module is based on a neural network which takes in input the normalized image segments of the basic symbols.

Music Notation Symbol Recognition – in this module the recognized basic symbols are mapped into the elementary components of music notation symbols.

Music Notation Model Refinement – once the elementary notation symbols are identified they are composed on the basis of a set of **Music Notation Rules**.

In this paper, only the module addressing the problems of segmentation is discussed.

3. Hierarchical Segmentation

The projection profiles are widely used for the segmentation of textual documents and musical scores. In particular, the X-Y tree [5], [6] is a typical method using projection profiles in document analysis. An input image is recursively split into successively smaller blocks by alternating cuts in horizontal and vertical directions. Cuts are found by analyzing the thresholded projection profile. In the field of OMR

Figure 2. Cut Tolerance.

the projection profiles are used for both segmentation and recognition of music symbols.

In our approach, the staff lines do not need to be removed. Due to the presence of staff lines and beams the segmentation of symbols cannot be based only on a thresholded projection profile. The staff lines give a constant background to the profile, but beams and other symbols give rise to more complex profiles. In order to allow the correct location of cutting points, the projection profile is considered as a 1-D signal and processed by appropriate filters in order to remove the background due to staff lines and beams.

The segmentation approach defined is based on the alternate application of the same technique along X and Y axes. This results in a hierarchical decomposition of the image. At level 0, the music sheet is segmented for extracting the single music lines (staffs) by using a profile along Y axis. At level 1, each music staff is segmented in order to extract the main vertical image sections including the music symbols and their related components. In this case, we use an X projection profile. At level 2, the image segments are furtherly segmented in order to extract the basic graphical components of the music symbols. This last segmentation is performed along Y axis and results to be quite easy since the image segments produced by level 1 do not present relevant changes along Y axis. The image segments, which are sent to the second block of the O^3MR architecture, are extracted from level 1 (when the image segment cannot be furtherly decomposed) and level 2.

3.1. Segmentation: Level 0

The projection along Y axis presents several evident peaks corresponding to the staffs. Typically, five peaks are observed for the presence of staff with five lines. However, when noise is present, or the image is rotated, the peaks related to staff lines are smeared. By thresholding the projection profile, the single pentagrams can be detected and extracted.
In several cases, there are many symbols above or below the staff that belong to it. For example, words of songs, wedges, long slurs. If a low value of threshold is used, the presence of these components makes the separation of staffs very hard. On the other hand, if a relatively high threshold value is used, they are cut out of the staff subimage (Figure 1a). In order to avoid this problem, a cut tolerance (that expands the cut region by a fixed amount) has been introduced. This mechanism, is also adopted in other levels to make the segmentation more robust (Figure 2). When the music sheet results to be very dense along the Y axis, successive image segments including staffs may be partially overlapped. In this case we adopted a *merge* approach that considers that two consecutive segments which are partially overlapped for the presence of a cut tolerance can be merged together when they are overlapped for more than a fixed value: the *merging value* (Figure 1c). This approach has to be carefully used since it can bring to merge all segments together making the segmentation phase unuseful.

Peaks followed by very deep holes along the profiles can generate incorrect segmentations if a simple thresholding approach is used. In general, filtering the projection profile with a low-pass filter can solve this problem (Figure 1b). For the projection profile smoothing, classical low-pass filters can be applied such as the simple running mean or the Gaussian. The second solution is the most effective since it

Figure 3. Level 1: the gray line reports different offset levels corresponding to the presence of beams.
Figure 4. Level 1: the segmentation obtained with the Unsharp Gaussian filter (in the middle). The original histogram is reported below.

maintains the most relevant features of the projection profile.

3.2. Segmentation: Level 1

Once the staffs are extracted the projection technique can be applied along the X axis (Figure 3). The segmentation at this level is more complex since it includes all problems that can be found in the other levels. The projection profile shows an offset due to the presence of staff lines. Moreover, the profile usually presents a set of different levels of offset corresponding to beams and other horizontal music symbols: wedges (*diminuendo*, *crescendo*), slurs, ties, text, etc. These symbols may also be nested each other and thus several offset levels are generated, producing strong discontinuities in the projection profile (Figure 3).

The projection profile is also characterized by a set of small hills due to the presence of noteheads and other music symbols. Most of these symbols are typically all of the same wide. Exception to these rules are the barlines (bars that mark the end of the measures) and the clefs. The goal of the segmentation at this level is to extract the single image segment containing only one symbol along the X axis. This can be done with a unique threshold once removed the offset with a filtering of the profile. However, note that the offset cannot be automatically determined by using filtering or other mechanisms without smoothing the projection profile and thus losing information.

The goal of filtering is to remove the peaks due to the presence of horizontal symbols leaving the information related to small symbols: noteheads, alternations, accents, etc. In Figure4, the typical results obtainable with the solution chosen (a high-pass Gaussian Unsharp filter) are shown.

Figure 5. Level 2: two typical examples of segmentation.

3.3. Segmentation: Level 2

This level of segmentation is quite simple since the image segments do not contain information along the other axis (or this information is very low) as it can be observed in Figure5. In this case, the only information along the Y axis is due to the presence of the note stem. Even in this case, we decide to extract the single graphical components. For example, the notehead, the staff lines cut by stem, the lines due to the beams and due to the *crescendo*, etc.

4. Experimental Results

The experiments have been performed on several music sheets printed with different fonts and formats. Some high-pass filters are compared on the basis of their effect on three projection profiles particularly complex: a complete pentagram and two *measures* that are very interesting for the shape of the corresponding projection profiles. In Figure 6, the filtered profiles together with extracted regions, are reported. The segmentation is evaluated by an *Efficiency Factor* (*EF*), that is the ratio between the number of elementary regions correctly found by the system, and the number of regions identified by a human supervisor. In the complete pentagram we found 48 regions, whereas in the tests of Figure 6 we detected 12 and 15 elementary regions, respectively. In the following, we briefly review the filters employed and the results obtained (Figure 6 and Table 1).

Unsharp filtering. Unsharp filters are based on the substraction of the original signal with the output of a low-pass filter applied to the original signal. The resulting high-pass effect cuts out the regular parts of the profile. **Unsharp Gaussian.** The signal in correspondence of elementary regions maintains its pattern after the filtering. This filter provided best results, among those tested. Note that in parts of the profile with constant trend some additional waves are introduced. However these artifacts have no effect since they remain below the level of discontinuities. **Unsharp Linear.** The filtered projection profile is more noisy than that obtained with the Gaussian Unsharp, giving rise to some "bad" cuttings. In general, there is a greater sensibility to additional horizontal elements (e.g., horizontal text).

Gradient filtering. Gradient filters are based on derivative processing, and enhance the portions of the profile with
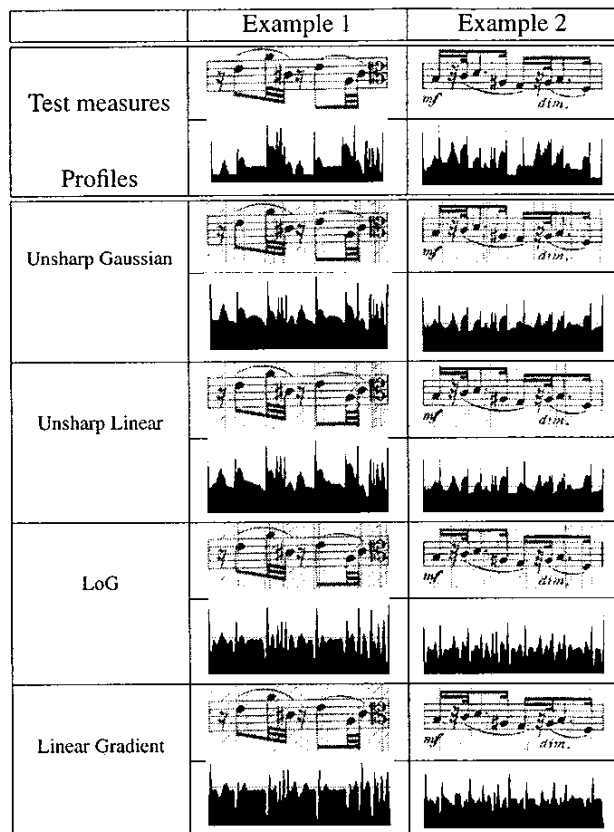

Figure 6. Segmentations obtained by some high-pass filters applied on the original projection profile.

Filter	EF		Width
	Score	Ex 1	Ex 2	
Unsharp Gaussian	0.95	0.77	1.00	101
Unsharp Linear	0.87	0.69	0.86	81
Gaussian Gradient	0.45	0.30	0.13	15
Sinusoidal Gradient	0.29	0.23	0.26	11
Linear Gradient	0.47	0.23	0.33	9
Stochastic Gradient	0.43	0.15	0.40	7
Laplacian of Gaussian	0.85	0.53	1.00	19

sults where obtained with Gaussian Unsharp filter.

The O^3MR project is being developed in all their parts. In particular, a connectionist architecture based on feed-forward neural networks has been implemented for the module of **Basic Symbol Recognition**, and interesting results have been obtained.

rapid variations, corresponding to strips. With gradient filters, we have both positive and negative peaks, and these filters cannot be profitably used since they allow to locate the position of discontinuities, but not their size.

Laplacian filtering. The LoG filter (*Laplacian of Gaussian*), is based on the second derivative of Gaussian function. With respect to Gradient filters the variations of profile are also located in wider intervals. A limit of this filter is the high sensitiveness to noise. The main limitation is that some regions containing a note head are split in two parts.

5. Conclusions

In addition to the test cases reported in Section 4 we made an extensive experimentation for the segmentation of many music scores with various difficulties. The tests where supported by an appropriate tool that was developed to easily compare various approaches. High levels of confidence where reached, and in all these experiments best re-
